Abstract. The purpose of the paper is to present some convergence properties of the iterative aggregation-disaggregation method for computing a stationary probability distribution vector of a column stochastic matrix. A sufficient condition for the local convergence property and the corresponding rate of convergence are established. Some global convergence considerations are presented. Several illustrative examples are included.

1 Introduction

The iterative aggregation-disaggregation (IAD) method presented in this paper belongs to a class of multilevel methods for solving linear systems \([2, 11, 12]\). We use this approach to find the stationary probability distribution vector of a stochastic matrix, i.e. the aim is to find a vector \(\hat{x}\) such that

\[B\hat{x} = \hat{x},\]

where \(B\) is a column stochastic matrix and \(\hat{x}\) is appropriately normalized. The typical characteristic within the class mentioned is that the corresponding basic iteration matrix is a polynomial in \(B\). This property allows to analyze this type of IAD methods in more detail. In particular, we show that we are able to control the number of relaxations on the fine level (Theorem 1).

We present some results on convergence analysis of IAD method. After introducing notations, in the second part, we present sufficient conditions for local convergence for one of the simplest form of the IAD method and we derive the asymptotic rate of convergence for this case. We show that when \(B\) contains at least one strictly positive row then there exists a neighborhood of \(\hat{x}\) such that for every initial approximation in it, the IAD method yields a sequence which converges to \(\hat{x}\). The result is compared with an iterative IAD method which uses partitioning into two groups and thus it can be analysed deeper \([5]\). Two examples show that the divergence

\(^1\)Corresponding author.
of the IAD method might be explained in some cases similar to the two groups case. Our analysis shows that the iteration process investigated in [4] can be treated as a particular case of the scheme shown in [8,9]. This explains appearance of some of its additional properties if the special method compared with the more general IAD methods. On the other hand, some of the tools applied in [4] can be utilized to analyzing more general situations as we show on two examples demonstrating possible divergence of a class of IAD methods with the power method with $B$ as the basic iteration. The second result concerns the global convergence. In section 4, a sufficient condition for the global convergence property of IAD method is shown. In the end of the paper, the relation to previous results and to some other IAD methods are discussed.

2 Definitions and basic relations

Let $B$ be an $N \times N$ column stochastic matrix, irreducible and not cyclic (for definitions see e.g. [1, 12]). Then according to [1, 12, 14], matrix $B$ possesses a simple eigenvalue 1 and the other eigenvalues are smaller than 1 in the modulus. The eigenvector $\hat{x}$ corresponding to the eigenvalue 1 is strictly positive and it is called the stationary probability distribution vector of matrix $B$.

Let $Q$ and $Z$ denote the spectral decomposition of $B$, fulfilling $B = Q + Z$, $Q^2 = Q$, $QZ = ZQ = 0$ and $\lim_{k \to \infty} Z^k = 0$. Matrix $Q$ is the projection matrix corresponding to the eigenvalue 1. Note that $B\hat{x} = \hat{x} = Q\hat{x}$.

In this paper, $||.||$ denotes the 1-norm, $||M|| = \max_{j=1,\ldots,N} \sum_{i=1}^{N} |M_{ij}|$, $r(M)$ denotes the spectral radius of a matrix $M$ ([4]) and $e$ is the vector of ones, $e = (1, \ldots, 1)^T$, the size of the vector can change according to the context.

Now we introduce the IAD method. Let $G_1, \ldots, G_n, n \leq N$, be the aggregation groups of events numbered with 1, 2, \ldots, $N$. The sets $G_i, i = 1, \ldots, n$, are considered to be disjoint and $\bigcup_{i=1}^{n} G_i = \{1, 2, \ldots, N\}$.

Let us define the restriction (aggregation) $n \times N$ matrix $R$, $R_{ij} = 1$ if $j \in G_i$ and $R_{ij} = 0$ otherwise. For any positive $x$ the prolongation (disaggregation) $N \times n$ matrix $S(x)$ is defined by

$$S(x)_{ij} = \frac{x_i}{\sum_{k \in G_j} x_k}$$

if $i \in G_j$ and $S(x)_{ij} = 0$ otherwise. Let $P(x)$ be the projection matrix given by $P(x) = S(x)R$. Note that $RS(x) = I$, $I$ is the identity matrix. Finally let $T = M^{-1}W$ be a matrix arising from some splitting of $I - B$ which is of weak nonegative type, i.e. $M^{-1}W \geq 0$ [1].

We will use the following relations. When $z$ is a positive $n \times 1$ vector, $||z|| = 1$, then $S(x)z$ is a positive $N \times 1$ vector satisfying $||S(x)z|| = 1$. Multiplying any nonnegative vector $x$, $||x|| = 1$, by matrix $Q$, we obtain $\hat{x}$, which is equal to any column of $Q$. Then also $QS(x)z = \hat{x}$ and $QP(x) = Q$. On the other hand, $P(x)Q \neq Q$ in general, but $P(\hat{x})Q = Q$.

The IAD method consists of several repeating steps. A description of the IAD algorithm considered in this paper follows. Here, the upper vector index denotes an order of the vector
Algorithm 1. (IAD method.)

Step 1. An elementwise positive initial approximation $x^0$, $||x^0|| = 1$, is selected. The value of $k$ is set to 0.

Step 2. A positive integer $s$ is chosen and the $n \times n$ aggregated matrix

$$RB^sS(x^k)$$

is constructed. The associated problem is solved, i.e. the vector $z$ is found, which fulfills

$$RB^sS(x^k)z = z,$$

$||z|| = 1$. This step can be called solution on the coarse level.

Step 3. The prolonged vector $x^{k+1,1}$ of the original size $N$ is computed by

$$x^{k+1,1} = S(x^k)z.$$

Step 4. The next approximation $x^{k+1}$ is computed by $x^{k+1} = T^t x^{k+1,1}$ for the appropriate positive integer $t$. This step can be called the smoothing step or the correction on the fine level.

Step 5. The test for convergence is evaluated and then the algorithm finishes with the approximate solution $x^{k+1}$ or continues with Step 2 and with $k$ increased by 1.

Note that the all computed vectors $x^k$ are positive. For any positive $x$, the aggregated matrix $RB^sS(x)$ is stochastic, irreducible and it is not cyclic. The latter property is a consequence of the acyclicity of $B$ [9, 10]. Computing $z$ in Step 2 is assumed to be carried out exactly. In place of the iteration matrix $T$ one can choose any nonnegative matrix with the properties $T\hat{x} = \hat{x}$ and $I - T = M(I - B)$ with some invertible $M$. Of course, the more sophisticated correction (Step 4) requires more time, but also achieves faster convergence. For example, $M$ can equal to $I$, $M$ can be the block diagonal part of $I - B$ or $M$ can equal to the sum of the lower block triangle and the block diagonal of $I - B$, etc. Then Step 4 with one of the three mentioned above smoothing methods is referred as power method, block Jacobi method and block Gauss-Seidel method respectively. Using the notation from [10], Algorithm 1 can be identified as SPV($B$; $I$, $B$; $P(x)$; $s$, $T$; $x^0$; $\epsilon$).

We now derive an operator which controls the convergence of Algorithm 1.

Lemma 1. The approximations $x^k$ given by Algorithm 1, $k = 0, 1, 2, \ldots$, follow the formula

$$x^{k+1} - \hat{x} = J(x^k)(x^k - \hat{x}),$$
where
\[ J(x) = T^t(I - P(x)Z^s)^{-1}(I - P(x)). \]

**Proof.** The proof can be found in [9, 10] but for the completeness, we present it here. Note that \( I - RZ^sS(x_k) \) is invertible due to the absence of 1 in the spectrum of \( Z^s \) and thus in the spectrum of \( RZ^sS(x_k) \). More precisely, if it was
\[ RZ^sS(x_k)u = u \]
for some \( x > 0 \) and nonzero \( u \), then for \( v = S(x)u \), we have \( v \neq 0 \) and
\[ P(x)Z^sv = v. \]

Having \( QP(x) = Q \) and multiplying this equation by \( Q \) from the left, we see that \( Qv = 0. \) Then we have
\[ P(x)Z^sv + P(x)Qv = P(x)B^sv = v \]
which means that \( v \) is an eigenvector of the irreducible stochastic matrix \( P(x)B^s \) corresponding to its eigenvalue 1, thus \( v > 0. \) But \( v > 0 \) contradicts \( Qv = 0. \) Then \( RZ^sS(x_k)u = u \) cannot be the case for any nonzero \( u. \) Continuing with the derivation of \( x^{k+1} \), we can write
\[
\begin{align*}
RB^sS(x^k)z &= z \\
RZ^sS(x^k)z + RQS(x^k)z &= z \\
(I - RZ^sS(x_k))^{-1}R\hat{x} &= z.
\end{align*}
\]

We have
\[
x^{k+1,1} = S(x^k)z = S(x^k)(I - RZ^sS(x^k))^{-1}R\hat{x} = (I - P(x^k)Z^s)^{-1}P(x^k)\hat{x}.
\]

The approximation error vector of \( x^{k+1} \) satisfies
\[
x^{k+1} - \hat{x} = T^tS(x^k)z - \hat{x} = T^t(I - P(x^k)Z^s)^{-1}P(x^k)\hat{x} - \hat{x}.
\]

Reminding that \( T^t\hat{x} = \hat{x} , \ Z\hat{x} = 0 \) and \( P(x^k)x^k = x^k \), we have
\[
\begin{align*}
x^{k+1} - \hat{x} &= T^t(I - P(x^k)Z^s)^{-1}P(x^k)(I - Z^s)\hat{x} - \hat{x} = \\
&= T^t(I - P(x^k)Z^s)^{-1}(I - P(x^k)Z^s + P(x^k) - I)\hat{x} - \hat{x} = \\
&= T^t(I - P(x^k)Z^s)^{-1}(I - P(x^k))(x^k - \hat{x}).
\end{align*}
\]

The proof is complete.

**Lemma 2.** If \( T = B \) and \( t \geq s \) then
\[ J(x) = B^{t-s}K(x), \]
or equivalently
\[ J(x) = Z^{t-s}K(x), \]

\[ 4 \]
where $K(x)$ can be expressed recurrently

$$K(x) = B^x(I - P(x) + P(x)K(x))$$

or equivalently

$$K(x) = Z^x(I - P(x) + P(x)K(x)).$$

**Proof.** We have

$$J(x) = B^t s K(x) = B^t s B^x(I - P(x)Z^x)^{-1}(I - P(x)),$$

then

$$K(x) = B^x(I - P(x)Z^x)^{-1}(I - P(x)) =$$

$$= B^x(I - P(x)) + B^x P(x)Z^x(I - P(x)Z^x)^{-1}(I - P(x)) =$$

$$= B^x(I - P(x)) + B^x P(x)B^x(I - P(x)Z^x)^{-1}(I - P(x)) =$$

$$= B^x(I - P(x)) + B^x P(x)K(x).$$

The both equivalencies in the proposition follow immediately from $B^k = Q + Z^k$ for any positive integer $k$. This completes the proof.

3 Local convergence condition

In this section we consider the IAD method with its simplest basic iteration matrix. We consider $T = B$ and $s = t = 1$ in *Algorithm 1*, up to some cases, where $T$, $s$ and $t$ will be assign explicitly. We show a sufficient condition for the local convergence, i.e. we find out under what circumstances there exists a neighborhood of $\hat{x}$ that for every $x^0$ in it, the *Algorithm 1* results in a sequence of vectors convergent to $\hat{x}$. In [12], it is shown that the exact solution $\hat{x}$ is the fixed point of the IAD method. But the exact convergence conditions has not yet been established. There are more results available for the case of partitioning into just two groups [5, 6, 7]. Unfortunately they mostly cannot be used for the $n$ groups case.

**Proposition 1.** Let $B$ contain at least one positive row, $B \geq b e^T$, $b \geq 0$, $|b| = \delta$ and $\delta \in (0, 1)$. Then for $T = B$ and $s = t = 1$, matrix $J(x)$ can be expressed in the form

$$J(x) = (B - be^T)(I - P(x)(B - be^T))^{-1}(I - P(x)).$$

**Proof.** The proof is similar to the proofs of Lemma 1 and Lemma 3 then we can proceed faster. We have

$$RBS(x^k)z = z$$

$$R(B - be^T)S(x^k)z + Rb = z$$

$$(I - R(B - be^T)S(x^k))^{-1}Rb = z$$
since $e^T z = 1$. The invertibility of $I - R(B - be^T)S(x^k)$ follows from $R(B - be^T)S(x^k) \geq 0$ and $||R(B - be^T)S(x^k)|| = 1 - \delta$. Then the error vector of $x^{k+1}$ is

$$x^{k+1} - \hat{x} = BS(x^k)(I - R(B - be^T)S(x^k))^{-1}Rb - \hat{x} = (B - be^T)S(x^k)(I - R(B - be^T)S(x^k))^{-1}Rb + b - \hat{x} = (B - be^T)P(x^k)(I - (B - be^T)P(x^k))^{-1}b + b - \hat{x} = (I - (B - be^T)P(x^k))^{-1}b - \hat{x} = (I - (B - be^T)P(x^k))^{-1}(b - \hat{x} + (B - be^T)P(x^k)\hat{x}) = (I - (B - be^T)P(x^k))^{-1}(B - be^T)(P(x^k) - I)\hat{x} = (B - be^T)(I - P(x^k)(B - be^T))^{-1}(I - P(x^k))(x^k - \hat{x})$$

which finishes the proof.

Let us stress, that if $B$ is elementwise positive and $B \geq \delta Q$, then

$$J(x) = (B - \delta Q)(I - P(x)(B - \delta Q))^{-1}(I - P(x)).$$

This is a straightforward consequence of Proposition 1, when considering $be^T = \delta Q = \delta \hat{x}e^T$.

**Definition 1.** For any positive vector $v$, we denote by $||M||_v$ the value $\min\{\alpha; v^TM \leq \alpha v^T\}$. It can be called the matrix norm induced by the vector $v$.

Note that if matrix $M$ is elementwise nonnegative, $||M||_v \geq r(M)$ for any positive $v$ ([14], Theorem 2.9). The verification of this consists in the transformation of $M$ to a proper matrix similar to $M$ and in the application of Gershgorin theorem.

Now we prove the local convergence of the IAD method both for $B$ positive or for $B$ containing at least one positive row. The proof of the following proposition is based on some ideas presented in [8].

**Proposition 2.** Let $T = B$ and $s = t = 1$ in Algorithm 1.

- a) When $B \geq \delta Q$ for some $\delta \in (0, 1)$, then the spectral radius of $J(\hat{x})$ is less than or equal to $1 - \delta$.
- b) When $B \geq be^T$, $b \geq 0$, $||b|| = \delta$, $\delta \in (0, 1)$, then the spectral radius of $J(\hat{x})$ is less than or equal to $\sqrt{1 - \delta}$.

**Proof.** The beginning of the proof does not differ for the assumptions a) or b) respectively. We can denote $A = B - \delta Q$ or $A = B - be^T$. Note that $A \geq 0$ and $||A|| = 1 - \delta$ in both cases. For such $A$’s and for any positive vector $x$ we have from Proposition 1

$$J(x) = A(I - P(x)A)^{-1}(I - P(x)) = A(I - P(x)) + AP(x)A(I - P(x)A)^{-1}(I - P(x)) = A(I - P(x)) + AP(x)J(x).$$
For $x \geq 0$, let $D(x)$ be an $N \times N$ diagonal matrix in which $D(x)_{ii} = \sqrt{x_i}$, $i = 1, \ldots, N$. Denote $P_s(x) = D(x)^{-1}P(x)D(x)$, $J_s(x) = D(x)^{-1}J(x)D(x)$, $A_s(x) = D(x)^{-1}AD(x)$ and $x_s = D(x)^{-1}x$. Note that $x_s = D(x)e$. In this proof, the index $s$ will not denote an element of a vector, but a matrix or a vector obtained after the introduced transformation.

We now show that $P_s(x)$ is symmetric. Supposing $(P_s(x))_{ij} \neq 0$, we have $(P(x))_{ij} \neq 0$. From the notations in section 2, it follows that $i$-th and $j$-th events belong to the same aggregation group, say $G_k$. Then

$$(P(x))_{ij} = \frac{x_i}{\sum_{l \in G_k} x_l}$$

and thus

$$(P_s(x))_{ij} = \frac{\sqrt{x_i}}{\sqrt{x_j} \sum_{l \in G_k} x_l} = \frac{\sqrt{x_i x_j}}{\sum_{l \in G_k} x_l} = (P_s(x))_{ji}.$$  

We see that $P_s(x)$ is symmetric, thus it is an orthogonal projection [13].

For a proper $x$ we estimate an upper bound for $||A_s(x)||_2^2$, where $||.||_2$ is the spectral norm, $||M||_2 = r(M^TM)^{1/2}$. Recalling the construction of $A$, $e^T A = e^T B - \delta e^T Q = (1 - \delta)e^T$ or $e^T A = e^T B - e^T b e^T = (1 - \delta)e^T$ for the assumptions a) or b), respectively. Since

$$x_s^T A_s(x) = e^T D(x)^T D(x)^{-1} AD(x) = (1 - \delta)e^T D(x) = (1 - \delta)x_s^T,$$

it holds for the assumptions a) and b)

$$||A_s(x)||_{x_s} = 1 - \delta.$$  

Now we consider the assumptions of a) and b) separately. Under the assumption a) it holds $A\hat{x} = (1 - \delta)\hat{x}$ while under the assumption b) we have only $A\hat{x} \leq \hat{x}$. For $x = \hat{x}$

$$A_s(\hat{x})\hat{x}_s = D(\hat{x})^{-1}AD(\hat{x})D(\hat{x})^{-1}\hat{x} = D(\hat{x})^{-1}A\hat{x}.$$  

The last expression is equal to $(1 - \delta)\hat{x}_s$ in the case a) and it is less or equal to $\hat{x}_s$ in the case b). Thus $||A_s(\hat{x})||_{x_s}^2 = 1 - \delta$ for a) and $||A_s(\hat{x})||_{x_s}^2 \leq 1$ for b). Then

$$||A_s(\hat{x})||_2^2 = r \left(A_s(\hat{x})^TA_s(\hat{x})\right) \leq ||A_s(\hat{x})^TA_s(\hat{x})||_{x_s} \leq ||A_s(\hat{x})^T||_{x_s} ||A_s(\hat{x})||_{x_s}.$$  

This means that $||A_s(\hat{x})||_2^2 \leq (1 - \delta)^2$ under the assumption a) and $||A_s(\hat{x})||_2^2 \leq 1 - \delta$ under the assumption b). Let us stress that we have estimated $||A_s(x)||_2$ only for $x = \hat{x}$.

In the rest of the proof, we estimate the norm of $J_s(\hat{x})$. From

$$J(x) = A(I - P(x)) + AP(x)J(x)$$

it follows

$$J_s(x) = A_s(I - P_s(x)) + A_s P_s(x)J_s(x).$$

Since $P_s(x)$ is an orthogonal projection, for any $u$ [13]

$$||J_s(x)u||_2^2 = ||P_s(x)J_s(x)u||_2^2 + ||(I - P_s(x))J_s(x)u||_2^2 \leq$$

$$\leq ||P_s(x)J_s(x)u||_2^2 + ||(I - P_s(x))J_s(x)u||_2^2 \leq$$

$$\leq ||P_s(x)J_s(x)u||_2^2 + ||(I - P_s(x))J_s(x)u||_2^2 \leq$$

$$\leq ||P_s(x)J_s(x)u||_2^2 + ||(I - P_s(x))J_s(x)u||_2^2 \leq$$

$$\leq ||P_s(x)J_s(x)u||_2^2 + ||(I - P_s(x))J_s(x)u||_2^2 \leq$$

$$\leq ||P_s(x)J_s(x)u||_2^2 + ||(I - P_s(x))J_s(x)u||_2^2 \leq$$
Using $||A_s(x)||_2 \leq \omega$, $\omega = 1 - \delta$ for the case a) and $\omega = \sqrt{1 - \delta}$ in the case b),

$$||(I - P_s(x))J_s(\hat{x})u||_2^2 \leq \omega^2||u||_2^2 - (1 - \omega^2)||P_s(\hat{x})J_s(\hat{x})u||_2^2,$$

which yields

$$||(I - P_s(\hat{x}))J_s(\hat{x})||_2 \leq \omega.$$

Let $\lambda$ be any eigenvalue of $J_s(\hat{x})$ and $v$ be the corresponding eigenvector. Then $(I - P_s(\hat{x}))v$ is either zero or some eigenvector of $(I - P_s(\hat{x}))J_s(\hat{x})$ corresponding to eigenvalue $\lambda$. Thus $|\lambda| \leq \omega$. When $J_s(\hat{x}) = D(\hat{x})^{-1}J(\hat{x})D(\hat{x})$, the spectra of the matrices $J_s(\hat{x})$ and $J(\hat{x})$ do not differ. Thus $r(J(\hat{x})) \leq \omega$, which finishes the proof.

Because the spectral radius of a matrix is a continuous function of its elements, there exists a neighborhood of the exact solution $\hat{x}$ such, that for any $x$ in it, the spectral radius of $J(x)$ is less then one. Then for any $\epsilon > 0$ there exists a neighborhood of $\hat{x}$ and a matrix norm $||.||$, consistent to some vector norm, such that $||J(x)||_s \leq \omega + \epsilon$ for any $x$ in the neighborhood of $\hat{x}$. The value $\omega$ is less then 1 according to the assumptions of Proposition 2. This results in

**Theorem 1.** The Algorithm 1 is locally convergent when $T = B$, $s = 1$, $t = 1$ and $B$ contains at least one elementwise positive row. When $B \geq be^T$, $b \geq 0$, $||b|| = \delta$, $\delta \in (0,1)$, then the asymptotic rate of convergence is at least $\sqrt{1 - \delta}$. When $B \geq \delta Q$, $\delta \in (0,1)$, $Q$ is the Perron projection of $B$, then the asymptotic rate of convergence is at least $1 - \delta$. This means, that in each step the approximation error reduces asymptotically by factor $\sqrt{1 - \delta}$ or $1 - \delta$, respectively.

**Example 1.** This example shows that convergence of IAD methods is not guaranteed by the convergence of the basic iteration matrix without some demands upon the number of relaxations on the fine level. It is shown that there exist matrices, for which the IAD algorithm doesn’t converge even locally. Let

$$B = \begin{pmatrix} 1/2 & 0 & 1/2 \\ 1/2 & 0 & 1/2 \\ 0 & 1 & 0 \end{pmatrix}$$

and let the aggregation groups be $\{1\}$ and $\{2, 3\}$. Then the stationary probability vector is $\hat{x} = (1/3, 1/3, 1/3)^T$ and the spectrum of $B$ is $\sigma(B) = \{1, -1/2, 0\}$. We consider $T = B$ and $s = t = 1$ in Algorithm 1, then the spectrum of $J(\hat{x})$ is $\sigma(J(\hat{x})) = \{-1, 0, 0\}$. Thus the local convergence of IAD Algorithm 1 for $t = s = 1$ and $T = B$ is not ensured for this matrix, because of $r(J(\hat{x})) = 1$. Indeed, if we choose $x^0 = (1/2, 1, 1/2)^T$, then the algorithm results in the alternating sequence $x^0, x^1, x^0, x^1, \ldots$, where $x^1 = (0, 1, 0, 1)^T$. But we can also take any vector $\tilde{x}^0 = \hat{x} + \alpha(x^0 - \hat{x})$, for arbitrarily small positive $\alpha$, i.e. $\tilde{x}^0$ arbitrarily close to $\hat{x}$, as a starting vector and obtain again the oscillating sequence of approximations. Let us stress that the assumption of Theorem 1 (the positivity of at least one row of $B$) is not fulfilled and the local convergence condition doesn’t match in this example.

The behavior of IAD method in Example 1 can be also analyzed using a method described in [5], Algorithm 3. These two algorithms work identically in the case of Example 1. Let us
briefly introduce the Algorithm 3 here. The set of events is partitioned into two groups and, accordingly, matrix $B$ is (permuted and) partitioned, so that

$$B = \begin{pmatrix} B_{11} & B_{12} \\ B_{21} & B_{22} \end{pmatrix}.$$ 

The starting vector $x^0$ is chosen and a sequence of the approximations is generated by the formula

$$x^{k+1} = \tilde{\rho} \tilde{B} x^k,$$

where

$$\tilde{B} = \begin{pmatrix} 0 & (I - B_{11})^{-1} B_{12} \\ 0 & S \end{pmatrix}$$

where $I - S$ is the stochastic complement of $I - B_{11}$ in $I - B$, $S = B_{22} + B_{21} (I - B_{11})^{-1} B_{12}$ and $\tilde{\rho}$ is a normalizing factor chosen such that $||x^{k+1}|| = 1$. One can verify that in Example 1

$$\tilde{B} = \begin{pmatrix} 0 & 0 & 1 \\ 0 & 0 & 1 \\ 0 & 1 & 0 \end{pmatrix}.$$ 

None of the convergence conditions presented in [5], page 10, primitivity of $S$ or positivity of at least one diagonal element of $S$, doesn’t match in this example. Note that Algorithm 1 converges locally for $T = B^2$ and $r(J(\hat{x})) = \frac{1}{2}$ for this case.

The Algorithm 3 of [5] can be also viewed as a particular case of the IAD algorithm presented in this paper, where we consider $n - 1$ one-element aggregation groups and one aggregation group containing the rest of events $(N - n + 1)$ and where we take a one-step block Jacobi iteration for smoothing in Step 4.

A similarity of the Algorithm 3 of [5] and the IAD method presented in this paper for $T = B$ and $s = t = 1$ can be elucidated from the following lemma.

**Lemma 3.** The approximations obtained by the IAD algorithm, Algorithm 1, fulfill

$$BP(x^k)x^{k+1} = x^{k+1}.$$ 

**Proof.** Recalling the Algorithm 1 for $T = B$ and $s = t = 1$, we see that

$$RBS(x^k)z = z.$$ 

Multiplying by $BS(x^k)$ from left, we have

$$BP(x^k)BS(x^k)z = BS(x^k)z.$$ 

Since $BS(x^k)z = x^{k+1}$, we obtain validity of the required proposition.

Lemma 3 says that in fact, the IAD method solves the equation $BP(x^k)x^{k+1} = x^{k+1}$ in each step. We can partition matrix $BP(x^k)$ in accordance with partitioning Algorithm 3 of [5] and
get the stochastic complement formulation. Let us suppose two aggregation groups and the corresponding partition of the matrix $P(x^k)$,

$$P(x^k) = \begin{pmatrix} P(x^k)_1 & 0 \\ 0 & P(x^k)_2 \end{pmatrix}.$$

Then we denote

$$\tilde{B}_{IAD}(x^k) = \begin{pmatrix} 0 & (I - B_{11}P(x^k)_1)^{-1}B_{12} \\ 0 & S_{IAD}(x^k) \end{pmatrix} \begin{pmatrix} 0 \\ P(x^k)_2 \end{pmatrix},$$

where $S_{IAD}(x^k) = B_{22} + B_{21}P(x^k)_1(I - B_{11}P(x^k)_1)^{-1}B_{12}$. If we take any nonnegative column vector of size equal to size of $B_{22}$ and multiply it by $\tilde{B}_{IAD}(x^k)$, then we obtain the solution of $BP(x^k)x = x$, i.e. approximation $x^{k+1}$ up to a multiplicative constant. Note that while in Algorithm 3 one iteration with $\tilde{B}$ yields the next approximation (up to a multiplicative constant) of the exact solution of $Bx = x$, one iteration with $\tilde{B}_{IAD}(x^k)$ gives the exact solution of $BP(x^k)x = x$ (up to a multiplicative constant), and thus the next approximation of Algorithm 1. So that, Algorithm 3 of [5] and Algorithm 1 for $T = B$ and $s = t = 1$ are identical if $\tilde{B}_{IAD}(x^k)$ doesn’t depend on $k$ and $B = \tilde{B}_{IAD}(x^k)$. When $S_{IAD}(x)$ doesn’t depend on $x$ and is cyclic, then the IAD method may not converge for some initial approximation. Another case of absence of convergence is presented in the following example.

**Example 2.** $B$ is given by

$$B = \begin{pmatrix} 0 & 1 & 0 & 1/2 \\ 1/2 & 0 & 0 & 0 \\ 1/2 & 0 & 0 & 1/2 \\ 0 & 0 & 1 & 0 \end{pmatrix}$$

and the aggregation groups are $\{1, 2\}$ and $\{3, 4\}$. Suppose again $T = B$ and $s = t = 1$. We let to the reader to show the oscillation in the sequence of approximations obtained by Algorithm 1 for some initial vectors $x^0$.

As shown in [10] there is a lot of free parameters in the IAD algorithm. A crucial role in the convergence issues is played by an interplay between the combinatorial properties of the original stochastic matrix and the basic iteration matrix projected by the complementary aggregation projection. For classical basic iteration schemes it is nicely shown in [3]. From this viewpoint it seems interesting that the schemes with aggregating $\{1\}$ and $\{2, 3\}$ in Example 1 and $\{1, 2\}$, $\{3, 4\}$ in Example 2 offer divergent processes with $B$ as basic iteration matrix while IAD processes with the same aggregation but different basic iteration matrix may converge rapidly. This is the case when one chooses the block diagonal Jacobi iteration process as the basic. Then the exact solution is returned after at most two iteration sweeps. The rapid convergence is caused by suitable choice of aggregation and the fact that the off-diagonal blocks are special rank-one matrices (see [10]).

## 4 Global convergence of IAD method

We start with an example.
**Example 3.** We are given a $3 \times 3$ stochastic matrix $B$,

$$
B = \begin{pmatrix}
\frac{1}{12} & \frac{10}{12} & \frac{1}{12} \\
\frac{1}{12} & \frac{1}{12} & \frac{1}{12} \\
\frac{10}{12} & \frac{1}{12} & \frac{10}{12}
\end{pmatrix}.
$$

The aggregation groups are $\{1, 2\}$ and $\{3\}$. Assume the positive vector $x, x = (\frac{10}{12}, \frac{1}{12}, \frac{1}{12})^T$, and construct the projection matrix $P(x), P(x) = S(x)R$, where

$$
S(x) = \begin{pmatrix}
x_1/(x_1 + x_2) & 0 \\
x_2/(x_1 + x_2) & 0 \\
0 & 1
\end{pmatrix}
$$

and

$$
R = \begin{pmatrix}
1 & 1 & 0 \\
0 & 0 & 1
\end{pmatrix}.
$$

Let $T = B$ and $s = t = 1$ in *Algorithm 1* and let $J(x)$ be the matrix of Lemma 1,

$$
J(x) = Z(I - P(x)Z)^{-1}(I - P(x)).
$$

Then the spectral radius of $J(x)$ for given $x$ is about 0.0732. But when the first two components of vector $x$ are switched, i.e. we consider vector $y = (\frac{1}{12}, \frac{10}{12}, \frac{1}{12})^T$, then the spectral radius of $J(y)$ increases to the value about 2.1429. Thus we can conclude, that in the proof of the global convergence for the case of $s = t = 1$ and $T = B$ in *Algorithm 1*, rather than the estimate of the spectrum of $J(.)$ an another technique should be adopted. Another possibility is to consider the *Algorithm 1* with more general $T$ and with larger $t$ and $s$.

**Lemma 4.** When $B^s \geq \delta Q, \delta \in (0, 1), T = B$ and $t \geq s$, then

$$
J(x) = B^t(I - P(x)V)^{-1}(I - P(x)) = B^{t-s}K(x),
$$

where $K(x) = V(I - P(x)V)^{-1}(I - P(x))$ and $V$ is the global core matrix corresponding to $B^s$ and $\hat{x}$.

**Proof.** The derivation can be done in the same manner as in the proofs of Lemma 1 and Lemma 2. The global core matrix [10] $V$ is here equal to $Z + (1 - \delta)Q = B - \delta Q$.

As indicated in Lemma 1, for $T = B, t \geq s \geq 1$, the convergence of *Algorithm 1* depends on some norm of the operator $J$. From Lemma 2 and Lemma 4, we have

$$
||K(x)|| \leq ||V|| ||I - P(x)|| + ||V|| ||P(x)|| ||K(x)||,
$$

thus

$$
||K(x)|| < \frac{2(1 - \delta)}{\delta},
$$

because of $||V|| = 1 - \delta, ||I - P(x)|| < 2$ and $||P(x)|| = 1$ for any positive $x$. 
So that the sufficient condition for the global convergence of IAD can be $(1 >) \delta \geq \frac{2}{3}$, i.e. $B^s \geq \frac{2}{3}Q$. This restrictive condition may often not be matched. In such a case, the value $t$ in $J(x) = B^{t-s}K(x)$ can be estimated to ensure $\|J(x)\| < 1$. Having $B^s > 0$, the lower bound of $\delta$ is estimated by the minimal element of matrix $B^s$, $\delta \geq \min\{(B^s)_{ij}; i, j = 1, \ldots, N\}$.

**Lemma 5.** When $B^s \geq \delta Q$, $\delta \in (0, 1)$, $T = B$, $t \geq s$, then $\|J(x)\| < 1$ for any $x > 0$ if

$$t \geq s \frac{\ln \delta - \ln 2}{\ln(1 - \delta)}.$$

**Proof.** The proposition can be verified by direct computing the exponent $t$ such that $t - s \geq sk$ where $(1 - \delta)^{k}2(1 - \delta)/\delta < 1$.

It can be seen, that when $B^s \geq \delta Q$, $\delta$ is close to 0 and the global convergence is to be ensured, then the exponent $t$ in Step 4 in Algorithm 1 must be of the value approximately $\frac{\ln \delta}{\ln(1 - \delta)}$. On the other hand, the power method converges globally with the convergence rate $1 - \delta$ when $B \geq \delta Q$. From this point of view, IAD method doesn’t seem to behave better then the power method. But the advantage of IAD methods insits in proper partitioning techniques, as shown e.g. in [2, 6, 9, 10, 11, 12].

## 5 Conclusions and discussion

In this paper we derived a sufficient condition for local convergence of the IAD method represented by Algorithm 1 when considering $T = B$ and $s = t = 1$, i.e. the smoothing step is represented by one-step power iteration with matrix $B$. This condition is positivity of at least one row of $B$. In addition to it, an upper bound of the asymptotic rate of convergence is derived. It is $1 - \delta$ when $B \geq \delta Q$ and it is $\sqrt{1 - \delta}$ when $B \geq bd^T$, $b \geq 0$ and $\|b\| = \delta$, $\delta \in (0, 1)$. It means that the error of the $k$-th approximation asymptotically reduces by the factor $(1 - \delta)^k$ or $\sqrt{1 - \delta}$, respectively.

This new results correct the convergence theorem of [9]. In [9] it was shown that the spectral radius of $(I - P(x))Z$ is smaller than one for $x$ equal to the exact solution $\hat{x}$. But we have shown that there exist irreducible primitive matrices $B$ for which $r((I - P(\hat{x}))Z) = 1$. The error vector formula shows that a necessary condition for convergence of the Algorithm 1 is the zero-convergence of matrix $(I - P(x))Z$. An immediate consequence of Theorem 1 is a bound for spectral radius of $(I - P(x))Z$, which is $\sqrt{1 - \delta}$ for the case of $B$ possessing at least one strictly positive row with the minimal element equal to $\delta$, and $1 - \delta$ for the case of elementwise strictly positive $B$ with the minimum equal to $\delta$.

Some relations between the IAD method represented by Algorithm 1 and the Algorithm 3 analysed in [5] have been shown. We were inspired by the analysis in [5] to better understand the divergence issues of IAD methods in some cases. As principal we consider the problem of choosing a reasonable partitioning of a given stochastic matrix into the blocks, i.e. the choice of the aggregation groups. This problem remains still open. The establishing a more accurate local convergence sufficient condition for the partitioning into more than two groups of events is still also the open question.
The sufficient global convergence condition is derived. When \( t \) and \( s \) are sufficiently large, we obtain the global convergence of the IAD method. These derivations give rise to quite pessimistic estimates. Some very promising results are obtained for classes of stochastic matrices possessing special structure [10]. For problems with such matrices exact solutions are returned by the IAD algorithms including Algorithm 1 after at most two IAD iteration sweeps. The research in this area will be the subject of future work.
